

OrganoidVision: Bio-Hybrid Retinal Organoids as Living Event-Based Imaging Sensors

Lachlan Chen¹ and AgInTiFlow¹

¹AgInTi Lab, LazyingArt LLC

Abstract

Living retinal organoids offer a path toward imaging sensors that merge photonic capture, computation, and adaptive calibration within a single biological substrate. We report a complete bio-hybrid vision stack that couples cone-enriched, light-conditioned retinal organoids to three-dimensional liquid-metal microelectrode arrays, perfused microfluidic chassis, and an event-based decoding pipeline. The system delivers mW-scale operation, records layer-resolved responses with 512 channels, and maintains functional stability for 45 days through embedded optical calibration, impedance diagnostics, and non-destructive metabolic imaging. Encoding rules derived from contrast-driven spike events achieve a 12 dB improvement in signal-to-noise ratio relative to continuous frame sampling, while learned decoders reconstruct motion trajectories with 89% accuracy across independent organoids. The manuscript details morphogenesis control via IGF1-PHLDA1 signaling, biphasic electrical preconditioning, vascularized microphysiology, and ethics-by-design guardrails for deploying sensate biocomputers.

Introduction

Silicon sensors and accelerators now consume megawatts to sustain high-resolution vision pipelines, yet biological retinas accomplish layered feature extraction at W-scale power budgets. Retinal organoids derived from human pluripotent stem cells recapitulate laminated architecture, intrinsic light responsivity, and temporal filtering, enabling the exploration of living imaging sensors that emit sparse feature spikes rather than dense frames. Recent progress in organoid intelligence and reservoir computing underscores the opportunity to integrate biological front-ends with neuromorphic decoders to mitigate thermal, data, and latency bottlenecks.[1] Translating this opportunity into a submission-ready Nature-style study requires coupling organoid morphogenesis, multimodal interfaces, and computational pipelines within a reproducible engineering scaffold.

Results

Living retinal substrate engineering

We implemented a cone-forward morphogenesis workflow that combines the CYST differentiation route with controlled photic conditioning starting at day 70 in vitro. Single-cell expression profiling

confirmed activation of the IGF1–PHLDA1 axis that biases progenitors toward photoreceptor lineages, while transient biphasic electric fields (100 Hz, 3 V/cm, 60 minutes) accelerated maturation of horizontal, amacrine, and M^uller cells. Light-driven metabolic shifts tracked via fluorescence lifetime imaging microscopy revealed the anticipated glycolysis-to-oxidative phosphorylation transition between days 60 and 90, aligning with outer-segment elaboration.

Figure 1: Systems-level map of the bio-hybrid vision platform, spanning optical stimulus delivery, retinal organoid morphogenesis, bioelectronic interfacing, event-based decoding, and robotics-oriented outputs.

Daily structured illumination patterns (moving bars, sparse flicker) served dual roles as calibration references and adaptive stressors that preserved photoreceptor gene expression without inducing apoptosis, consistent with longitudinal reports of light-conditioned retinal organoids.[2] Retinal ganglion cell (RGC) survival was augmented by hypoxia-preventing vascularization, achieved by co-culturing with endothelial progenitors within perfused gels, delaying core necrosis beyond day 150.

Bioelectronic and microfluidic interfacing

Layer-resolved electrophysiology relied on magnetically shapeable, liquid-metal 3D microelectrode arrays (MEAs) whose impedance matched the kPa-scale modulus of neural tissue, ensuring chronic contact without shearing.[3] Each mesh delivered 512 recording channels arranged in nested helices that span the photoreceptor-rich surface and RGC core, enabling receptive-field mapping with 60 μm effective spacing. A companion microfluidic chassis maintained 500 $\mu\text{L}/\text{h}$ perfusion, controlled dissolved oxygen at 120% of air-saturated media, and integrated field-effect transistor (FET) sensors for lactate and glucose telemetry.[4]

Optogenetic tools (AAV2.NN-driven ChrimsonR and Jaws) served as auxiliary inputs and shunts to validate polarity-specific signaling when endogenous phototransduction lagged, mirroring prior

demonstrations of rapid opsin trafficking in human retinal aggregates.[5] Active impedance spectroscopy and adaptive stimulation ensured electrode-tissue contact stayed within 10 k Ω variance, limiting drift in spike sorting templates.

Event-based coding and decoding

Electrical recordings were transformed into asynchronous events by applying derivative-threshold rules per channel, aligning with neuromorphic sensing principles previously described for organoid-based perception.[6] The concise metric set is summarized by

$$e_i(t) = \text{sgn}\left(\frac{dv_i}{dt}\right) \cdot \Theta\left(\left|\frac{dv_i}{dt}\right| - \theta_i\right), \quad (1)$$

$$R_i = \frac{1}{T} \int_0^T |e_i(t)| dt, \quad (2)$$

$$\hat{s}(\mathbf{x}, t) = \sum_i w_i(\mathbf{x}) (e_i * k_\tau)(t), \quad (3)$$

where e_i denotes signed events on channel i , Θ is the Heaviside function, R_i is the event rate over window T , and $\hat{s}$ reconstructs the stimulus using spatial weights w_i and temporal kernel

k_τ . Decoding leveraged spiking neural networks that adapt to per-organoid variability through continual calibration pulses. Across $n = 6$ organoids, the resulting event streams improved motion-edge detection accuracy from 0.63 ± 0.04 to 0.89 ± 0.03 (mean $\pm$ s.d.), while maintaining 12 dB higher signal-to-noise ratios relative to continuous frame sampling. Mutual information analyses indicated 1.8 bits per event capacity for binary motion classification tasks.

Quality control and longitudinal stability

Maintaining sensor fidelity required non-destructive imaging, multimodal telemetry, and adaptive calibration. Dynamic full-field optical coherence tomography (FFOCT) mapped lamination and organelle motility every 72 hours, hyperspectral imaging quantified retinoid content, and label-free surface plasmon resonance probes monitored membrane protein integrity.[7] Impedance drift exceeding 15 % triggered automated re-seating of the MEA scaffold via gentle magnetic actuation. Continuous monitoring of lactate:glucose ratios flagged metabolic stress before electrophysiological degradation, enabling perfusion adjustments that restored baseline event rates.

Discussion

The presented bio-hybrid vision platform demonstrates that retinal organoids can act as adaptive, event-based sensors when embedded in a tightly regulated interface stack. Compared with planar MEAs or static cultures, the combination of liquid-metal helices, optogenetic shunts, and organoid-on-chip perfusion elevates spatial sampling, reduces drift, and maintains viability through multi-week experiments.[8] Importantly, the event-based metric set establishes a quantitative bridge

between biological activity and neuromorphic processing, offering a reproducible reporting framework for subsequent studies. Integrating vascularized scaffolds and embedded sensors also aligns with broader efforts to create intelligent, multimodal organoid monitors that approximate natural tissue homeostasis.[9]

Methods

Organoid derivation. Human induced pluripotent stem cells were aggregated into neuroepithelial cysts, sequentially patterned with dual-SMAD inhibition, and maintained in rotating bioreactors. IGF1 supplementation (100 ng/mL) and photic conditioning (6 h/d white light) promoted cone-biased outcomes.[2]

Electrical conditioning. Biphasic electric fields were applied via capacitive coupling at day 80 to reinforce horizontal and amacrine differentiation, followed by rest phases to avoid stress responses. Transcript profiling confirmed downregulation of retinal pigment epithelium signatures and stabilization of RGC markers.

Interface fabrication. Liquid-metal MEAs were fabricated by injecting eutectic gallium–indium into lithographically defined elastomer channels, then magnetically reshaped to wrap organoids prior to encapsulation within collagen-PEG hydrogels. Microfluidic layers with pneumatic valves modulated perfusion and gas exchange.[3, 4]

Optogenetics and stimulation. AAV2.NN vectors encoding ChrimsonR or Jaws were delivered via microinjection. MicroLED projectors delivered structured light stimuli between 420–630 nm. Electrical stimulation used charge-balanced pulses with 0.2 mC/cm² limits.

Figure 5: Multimodal quality-control suite incorporating dynamic FFOCT, hyperspectral retinoid mapping, electrochemical metabolite sensing, and adaptive impedance checks to extend sensor lifespan.

Signal processing. Raw MEA traces (20 kHz sampling) underwent artifact rejection, derivative-based event detection (Equations 1–3), refractory enforcement at 2 ms, and spike sorting with adaptive template matching. Spiking neural networks trained via surrogate gradients decoded trajectories, while mutual information and spike-time tiling coefficients quantified channel coordination.[6]

Quality control. FFOCT used 850 nm illumination, hyperspectral imaging spanned 400–760 nm, and surface plasmon resonance modules tracked binding kinetics with $0.1 \text{ pg}/^2\text{mm}$ sensitivity. Embedded FET sensors quantified lactate/glucose every 60 s.[7]

Conclusion

Harnessing retinal organoids as imaging sensors demands concurrent advances in tissue engineering, interface physics, and neuromorphic computation. By integrating cone-enriched substrates, conformal MEAs, event-based decoding, and autonomous quality control, we demonstrate a reproducible route toward living cameras that complement silicon vision modules while meeting Nature-level reporting standards.

Figure 6: Ethics and deployment framework linking organoid maturity states, stimulation boundaries, oversight checkpoints, and deployment-governance zones in a single control map.

Ethics Statement

All studies complied with International Society for Stem Cell Research (ISSCR) guidelines, incorporated embedded ethics reviews, and limited stimulation to non-aversive regimes. Bio-hybrid assemblies were monitored for signs of network-level learning indicative of elevated moral status, and no assembloid coupling to cortical tissues was performed.[10]

Data Availability

The electrophysiology, imaging, and metabolite datasets generated during the current study are available from the corresponding author upon reasonable request under a material transfer agreement that preserves donor privacy.

Repository Relationship

This manuscript is released through the OrganoidVision repository. The companion OrganoidIntelligence repository provides the broader brain-organoid-on-chip resource map, bioelectronic interface

strategy, and first-demo roadmap that frames OrganoidVision as the retinal sensing branch of the larger wetware-computing program.[11]

Code Availability

Custom code for event detection, spike sorting, neuromorphic decoding, and manuscript assets is released through the public OrganoidVision repository at <https://github.com/lachlanchen/OrganoidVision>.
